Short Communication

Effect of season and scion procuring on softwood grafting in sapota (Manilkara achras, Mill.)

Shashi Gritlahare and Ashutosh Anant

Abstract
The experiment was conducted at Horticulture Research Station, Orissa University of Agriculture & Technology, College of Agriculture, Bhubaneswar during 2016 - 2017. The treatment comprises of four grafting seasons (20th June, 20th July, 20th August and 20th September) and three scion procuring periods (0 days, 5 days and 10 days) have been tried in a Factorial Randomized Block Design with three replications. The results revealed that among the four grafting seasons, 20th July recorded the maximum growth of scion (2.64 cm and 4.69 cm at 60 and 120 DAG, respectively). In respect to different scion procuring periods, maximum growth of scion (2.61 cm and 4.69 cm) at 60 and 120 DAG, respectively, were observed in 10 days procured scions. The combined effect of the above two factors had also significant influence on this parameters studied.

Keywords: Sapota, procuring, softwood grafting

Introduction
Sapota (Manilkara achras Mill.) is one of the important fruit crops of tropical regions of the country. It prefers a warm and moist weather and grows both in dry and humid areas. It can tolerate salinity and water stress to a great extent. In sapota, various methods of propagation have been practiced with considerable success. Budding, air layering, approach grafting and softwood grafting are the methods of propagation followed in sapota. Softwood grafting on one year old rootstock seedling is simple, economical and can give considerable percentage of success (Amin, 1978) [1]. The different rootstocks used in propagation of sapota are Khirni or rayan, Adam’s apple, mahua, mee tree and star apple. Of all the rootstocks rayan or Khirni, a tropical tree, is the most suitable for Sapota. The ideal season of grafting in sapota is rainy season (July – September). Weather conditions play a prominent role on the success of grafting, influencing graft success and growth of grafted plant (Iqbal et al., 2004) [2]. Success, survivability and growth of grafts depend upon many other factors including variety, grafting method, time of grafting, age and procuring of scion, age of rootstock, leaf and node retention on rootstock and environmental conditions (Hartman et al. 1997) [4]. Precuring also plays an important role in the success of softwood grafting in sapota (Pampanna and Sulikeri, 2000) [5].

The present study was undertaken to see the effects of grafting season and scion defoliation period on the success of softwood grafting and survivability of grafts in sapota.

Materials and Methods
Khirnee seedlings of one year age raised in polybag were used as a rootstock for sapota softwood grafts. Healthy scion shoots free from pests and diseases were selected. Scion sticks were collected from the terminal shoot portions of sapota branches. The leaves were removed leaving the petioles attached to the shoots. The scions were procured (allowed to remain on the plant) for varying periods of 0, 5 and 10 days, i.e. for P1, P2 and P3, respectively. Procured scions of size 6-7 cm long were chosen. Softwood grafting was performed in four different grafting season (20th June, 20th July, 20th August and 20th September). The prepared grafts were shifted to the open condition and were maintained in good condition by removing off-shoots, polythene caps and polythene strip and controlling disease and pest. The data were collected on length of new scion growth.

Result and Discussion
Result presented in (Table 1) revealed that among different seasons grafting during the month of July shows maximum values in characters like length of scion growth both at 60
DAG (2.64 cm) and 120 DAG (4.69 cm). This may be due to the fact that in addition to photosynthates contribution towards the growth of the scion, it may be more helpful in month of July because of optimum temperature prevalence during the respective period resulting in good growth of scion as have been emphasized by Hartmann and Kester, 1972 [3]. Among the procuring period duration of scion wood studied, leaves defoliated ten days before softwood grafting recorded maximum values in characters like length of new scion growth at 60 and 120 DAG (2.61 cm and 4.67 cm, respectively). This might be due to the initiation of good cambial activity which might have resulted from defoliation (Hartman et al., 1997) [4]. The interaction between grafting season and scion procuring revealed that grafting on 20th July along with 10 days procured scion sticks recorded maximum values in characters like length of new scion growth at 60 and 120 DAG (2.72 cm and 4.84 cm, respectively which were significantly superior as compared to other treatment combinations.
